Project 2: Modelling daily cycling demand in Edinburgh

Group members: [Karthik Sutheeshkumar], [Kiet Lam], [Leon]

Word count: [0 words]

1 Introduction

Edinburgh operates a network of automatic cycling counters at strategic locations across the city that records the total number of cyclists passing each site daily, The resulting dataset contains 2,180 observations spanning from 2020 to 2025, covering a period that includes the COVID-19 pandemic and a gradual return to normal travel patterns. Using this data, we evaluate a sequence of linear regression models of increasing complexity rigorously to explain how daily cycling demand varies with weather conditions, day of week, seasonality, and longer-term trend, evaluating each model using leave-one-year-out cross validation. The analysis is guided by three questions of practical interest to Edinburgh City Council: how well the model predicts demand across different seasons, how sensitive cycling is to temperature, and what the long-term trend implies for infrastructure planning over the next decade.

2 Exploratory data analysis

Three derived variables are created before modelling. First, month is converted to an ordered factor with levels 1–12, ensuring plots display January to December in the correct order. Second, day of week is re-specified with explicit levels from Sunday to Saturday, overriding R's default alphabetical ordering. Third, a numeric trend variable is derived as the integer number of days elapsed since 1 January 2020, so that trend = 0 corresponds to the start of the observation period and increases by 1 for each subsequent day. This allows the model to capture any linear drift in cycling demand over 2020–2025.

Table 1 summarises the key numeric variables across the 2180 daily observations. Daily cyclist count average around 10,816 but with a large standard deviation of 4729 reflecting strong seasonal variation. The minimum and maximum count of 1,264 and 43,864 respectively confirm that demand varies dramatically across the year. Edinburgh's climate is characterized by mild but cool conditions, with mean daily temperatures averaging 9.7°C and ranging from -8.1°C to 23°C, typical for a Scottish city. The wide spread in temperature variables, ranging from -14°C to 31°C, suggests that weather conditions vary considerably across the observation period and are likely to play an important role in explaining day-to-day variation in cycling demand.

Table 1: Summary statistics for daily cyclist count and temperature variables.

Variable	Mean	SD	Min	Median	Max
Daily Count	10815.5	4728.9	1264.0	10531.0	43864
Mean Temp (°C)	9.7	4.8	-8.1	9.8	23
Min Temp (°C)	5.9	5.0	-14.0	6.0	18
Max Temp (°C)	13.2	5.3	-3.0	13.0	31

Figure 1: Time series of daily cyclist counts in Edinburgh (2020–2025) with a smoother.

Figure 1 shows the daily cyclist counts across the full observation period from 2020-2025, with a smoother overlaid to highlight the trend, filtering out day-to-day variability. We can see the obvious pattern that the daily count climbs every summer and fall back each winter, and this repeats every year. There is a visible dip around 2020-2021, which is unsurprising given the COVID-19 lockdowns during that period. After that, daily counts reach their highest levels around 2022-23. The drop at the end of the observation period coincides with the data ending in early 2026, making it difficult to distinguish a seasonal effect from a genuine trend change. Certain days stands out in count, especially one around 2022 that exceeds 40,000 cyclists a day, which probably reflects an unusually warm day.

Boxplots of count by month and by day of week

Figure 2: Distribution of daily cyclist counts by month.

Figure 2 confirms the seasonal pattern seen in the time series. Counts are lowest in January and December,

with medians around 10,500-11,500 cyclists per day, rising steadily through spring and peaking between May and August. Winter months see roughly half the cycling activity of summer months, which has clear implications for seasonal infrastructure planning.

Figure 3: Distribution of daily cyclist counts by day of week

Figure 3 suggests that cycling demand is higher on weekdays than weekends, with Tuesday to Friday showing the highest medians of around 11,000-12,000 cyclists per day. Sunday and Monday stand out as the lowest, with medians closer to 8,000-9,000, suggesting that commuting is a major driver of cycling demand in Edinburgh.

Scatter plot of count vs temp_mean

Figure 4: Daily cyclist count versus mean temperature

Figure 4 shows a clear positive but non-linear relationship between mean temperature and daily cyclist

counts. Counts rise steeply at lower temperatures before leveling off above around 10–12°C, suggesting a quadratic relationship for temperature term. The spread of counts also increases with temperature, suggesting heteroscedasticity.

Showing relation between count and mean temperature during COVID and post COVID period

Figure 5: Daily cyclist count versus mean temperature by COVID and post-COVID period (2020–2025)

Figure 5 reveals an interesting and somewhat counter intuitive pattern — cycling counts during the COVID period (2020-2021) were actually higher at warmer temperatures compared to post-COVID years, with the red smoother sitting well above the blue at temperatures above 10°C. This likely reflects that during the covid lockdowns, cycling shifted from commuting to recreational use, with people more willing to cycle on pleasant days but much less likely to cycle in cold or wet conditions, explaining the steeper temperature sensitivity. At cold temperatures the pattern reverses, with post-COVID counts higher, consistent with commuters cycling regardless of weather. This difference in behaviour between the two periods suggests that a COVID indicator variable may improve model fit, and motivates its inclusion as a candidate extension in M3.

3 Baseline model M0

In all of the models that we will fit, the response variable is $y_i = \text{count}_i$, the total daily cyclist count on date i, for each day i from 1 January 2020 to 31 December 2025. Four models of increasing complexity are considered: M0 (baseline with numeric month), M1 (adds linear trend and factor covariates), M2 (replaces linear temperature with a quadratic term), and M3 (log-transforms the response to address non-normality). The common predictors across all models are defined as follows:

$$
\begin{aligned}
x_{1i} &= \text{temp_mean}_i \quad \text{(daily mean air temperature in °C)} \\
x_{2i} &= \text{weekend}_i \quad \text{(binary indicator: 1 if Saturday or Sunday, 0 otherwise)} \\
m_i &\in \{1, \dots, 12\} \quad \text{(month: numeric in M0, factor in M1–M3)} \\
t_i &= \text{trend}_i \quad \text{(integer days since 2020-01-01, where } t_i = 0 \text{ on 1 January 2020)} \\
d_i &= \text{dow}_i \quad \text{(day of week factor, reference level: Sunday)}
\end{aligned}
$$

Table 2: Coefficients table for baseline model M0.

term	estimate	std.error	statistic	p.value
(Intercept)	10385.819	267.015	38.90	0
temp_mean	247.179	20.769	11.90	0
weekend	-1246.888	214.172	-5.82	0
month_num	-247.184	28.810	-8.58	0

All models assume $\varepsilon_i \sim N(0, \sigma^2)$.

The baseline model M0, fitted for each day i from 1 January 2020 to 31 December 2025, is specified as:

$$y_i = \beta_0 + \beta_1 x_{1i} + \beta_2 x_{2i} + \beta_3 m_i + \varepsilon_i, \quad \varepsilon_i \sim N(0, \sigma^2)$$

Table 2 shows the estimated coefficients for M0. All four predictors are highly significant ($p < 0.001$). Each 1°C increase in mean temperature is associated with approximately 247 additional cyclists per day with the other variables held fixed, while weekend days see around 1,247 fewer cyclists than weekdays, consistent with the commuter-driven pattern observed in the EDA. The negative month coefficient (-247) implies that daily count declines on average as the month increases, though this is a crude approximation since the relationship between month and demand is not linear.

Figure 6: Diagnostics for M0

The residuals versus fitted plot shows that the spread of residuals grows noticeably with fitted values, indicating heteroscedasticity — a violation of the constant variance assumption. The QQ plot reveals a heavy right tail, with standardized residuals curving sharply above the reference line at high quantiles, reflecting the right-skewed distribution typical of non-negative count data. Both issues suggest that M0's Gaussian assumption is inadequate.

M0 captures the broad direction of key predictors — temperature, weekend effect, and seasonality but treats month as numeric, forcing a linear relationship across months that does not reflect the true seasonal pattern seen in the EDA. It also omits day of week entirely and includes no long-term trend. These limitations motivate M1, which switches month to a factor, adds day of week as a factor, and introduces a linear trend term to capture drift in cycling demand over 2020–2025.

4 Proposed models M1–M3

4.1 Model M1: Trend and factor

Model M1, fitted for each day i from 1 January 2020 to 31 December 2025, is specified as:

$$y_i = \beta_0 + \beta_1 x_{1i} + \beta_2 x_{2i} + \beta_3 t_i + \sum_{m=2}^{12} \gamma_m \mathbf{1}(m_i = m) + \sum_{d=2}^{7} \delta_d \mathbf{1}(d_i = d) + \varepsilon_i, \quad \varepsilon_i \sim N(0, \sigma^2)$$

M1 extends M0 in three ways. First, month is switched from a numeric predictor to a factor, giving each month its own intercept. Figure 2 shows that the month–demand relationship is not monotonic, so forcing a single slope as M0 does is inappropriate. Second, day of week is added as a factor — the weekend binary in M0 groups Saturday and Sunday together, but Figure 3 shows these days behave differently, so a full factor allows each day its own effect. Third, a linear trend term t_i is added to capture the drift in underlying demand visible in Figure 1. Both factors use dummy variable encoding with January and Sunday as reference categories, so γ_m and δ_d represent differences relative to these baselines, and the sums begin at $m = 2$ and $d = 2$ as the first level of each factor is absorbed into β_0.

Diagnostics of M1

Figure 7: Diagnostics for M1

Compared to M0, M1 shows some improvement — the fitted values span a wider range, suggesting the additional predictors (trend, factor month, factor day of week) give the model more flexibility to capture variation in demand. However, the core issues persist. The residuals versus fitted plot still shows increasing spread at higher fitted values, indicating that heteroscedasticity remains unresolved. The QQ plot continues to show a pronounced right tail, with standardized residuals reaching above 6 at the upper end, reflecting the right-skewed nature of the count data that a Gaussian model struggles to accommodate. These issues motivate further extensions in M2 and M3.

4.2 Model M2: Nonlinear temperature

Model M2, fitted for each day i from 1 January 2020 to 31 December 2025, is specified as:

$$y_i = \beta_0 + \beta_1 x_{1i} + \beta_2 x_{1i}^2 + \beta_3 x_{2i} + \beta_4 t_i + \sum_{m=2}^{12} \gamma_m \mathbf{1}(m_i = m) + \sum_{d=2}^{7} \delta_d \mathbf{1}(d_i = d) + \varepsilon_i, \quad \varepsilon_i \sim N(0, \sigma^2)$$

M2 extends M1 by replacing the linear temperature term with a quadratic, adding both x_{1i} and x_{1i}^2 as predictors. Figure 4 shows that the temperature–demand relationship flattens above around 10°C, which a linear term cannot capture. The quadratic term allows the model to reflect this diminishing sensitivity, which is also physically plausible — once conditions are warm enough, further temperature increases have a smaller effect on cycling behaviour.

Figure 8: Diagnostics for M2

M2 shows marginal improvement over M1 — residual spread is slightly more even and the lower QQ tail follows the reference line more closely. However, the right tail worsens, with standardised residuals exceeding 7, and heteroscedasticity persists. The consistently heavy right tail across M0, M1, and M2 suggests a Gaussian model is fundamentally inappropriate for the given data, motivating the log transformation in M3.

4.3 Model M3: Log-Transformed Response

Model M3, fitted for each day i from 1 January 2020 to 31 December 2025, is specified as:

$$\log(y_i + 1) = \beta_0 + \beta_1 x_{1i} + \beta_2 x_{1i}^2 + \beta_3 x_{2i} + \beta_4 t_i + \sum_{m=2}^{12} \gamma_m \mathbf{1}(m_i = m) + \sum_{d=2}^{7} \delta_d \mathbf{1}(d_i = d) + \varepsilon_i, \quad \varepsilon_i \sim N(0, \sigma^2)$$

M3 keeps all predictors from M2 but log-transforms the response, fitting $\log(\text{count}_i + 1)$ rather than count_i directly. The persistent right-skew and heteroscedasticity seen across M0–M2 are classic symptoms of modelling non-negative count data with a Gaussian assumption.The log transformation addresses this by compressing large values, reducing skewness and stabilising variance. The +1 ensures the transformation is defined if any zero counts are present.

Figure 9: Diagnostics for M3

The diagnostic plots for M3 show a marked improvement — residuals are now scattered evenly around zero and the QQ plot follows the reference line closely across almost its entire range, compared to the severe right tail deviation in M2. Some deviation remains at both tails, indicating slight remaining non-normality, but the Gaussian assumption is considerably more plausible for M3 than any earlier model.

5 Evaluation

5.1 Statistical Performance

Table 3: Leave-one-year-out cross-validation scores for models M0–M3. Lower is better for all scores.

model	RMSE	MAE	DS	IS
M0	4740.9	3805.6	18.05	25630.5
M1	4602.3	3665.3	18.08	25391.0
M2	4587.6	3650.2	18.07	25277.9
M3	4530.8	3598.5	18.65	30353.6

Table 3 shows the CV scores across all four models. RMSE and MAE improve consistently from M0 to M3, with M3 achieving the lowest values of 4531 and 3598 respectively. However, M0 achieves the lowest

DS (18.0) and M3 the highest (18.5), with M3 also notably worse on IS. This disagreement arises because back-transforming M3's log-scale predictions inflates predictive variance via the delta method, penalising DS and IS. M3 is nonetheless selected as the final model — it achieves the best RMSE and MAE and is the only model whose diagnostic plots satisfy the normality and constant variance assumptions.

Table 4: Monthly cross-validated RMSE and Dawid–Sebastiani score for the final model M3.

Month	RMSE	DS
Jan	4377.6	18.16
Feb	3973.2	17.79
Mar	5886.6	18.77
Apr	6485.7	19.34
May	5035.7	18.27
Jun	3909.0	17.85
Jul	3485.3	17.52
Aug	5301.0	18.43
Sep	4270.3	18.20
Oct	4086.3	18.56
Nov	4310.5	18.59
Dec	4381.3	22.27

Table 4 shows that predictive performance varies across the year. RMSE is lowest in July (3485.3) and highest in April (6485.7) and March (5886.6), suggesting early spring is hardest to predict. December has the worst DS (0.92), indicating poorer uncertainty calibration around that period. Early spring and December therefore present the greatest challenge for the final model.

5.2 Practical Performance

5.2.1 Temperature effects and nonlinearity

Table 5: Comparison of nonlinear temperature specifications in the M2 model family.

temp_var	RMSE	DS	IS
temp_max	4599.1	18.09	25317.1
temp_mean	4587.6	18.07	25277.9
temp_min	4574.7	18.06	25010.3

Table 5 compares three nonlinear temperature specifications. `temp_min` performs best with the lowest RMSE (4574.7) and IS (25010.3), though DS is effectively identical across all three (difference of 0.03 at most). This is physically plausible — commuters are more likely to base cycling decisions on the coldest conditions of the day, making minimum temperature the most behaviourally relevant measure.

Table 6: Estimated marginal effect of a 1°C increase using the chosen temperature variable.

Temperature	Marginal.effect..cyclists.per..1C.
5C	53.9
15C	-250.2

Table 6 shows the marginal effects for the chosen specification. At 5°C, a 1°C increase is associated with approximately 53.9 additional cyclists per day. At 15°C, the model implies a decrease of 250.2 cyclists per day, though this more likely reflects the flattening curvature of the quadratic term at higher temperatures than a genuine reduction in cycling. As the model excludes a temperature × season interaction, this effect is assumed constant across the year.

5.2.2 Seasonal prediction accuracy

The purpose of this subsection is to assess how reliably the final model predicts cycling demand across the calendar year. Using the monthly cross-validation results from Table 4, we identify which months are predicted best and worst and consider what this implies for transport planning in Edinburgh.

As discussed in the Statistical Performance section, Table 4 shows that the predictive performance of the final model varies across the year. Prediction accuracy is strongest in summer, especially in June and July, where both RMSE and DS are lowest. The model performs worst in March and April on RMSE, while December has the highest DS, indicating poorer calibration of the predictive distribution. M3 is the best overall model, yet its performance is not equally reliable across all months.

A plausible transport-planning interpretation is that cycling demand is easier to predict in summer because behaviour is more stable and weather conditions are more consistently favourable. In winter, demand may also be somewhat easier to model for a different reason: for many people, conditions are already too cold or unpleasant for cycling, so small changes in temperature are less likely to affect the decision to bike at all. This reduces behavioural variation and makes demand more predictable. By contrast, early spring is likely to be harder to predict because it is a transition period. As temperatures begin to improve, people may differ much more in the point at which they feel conditions are "good enough" to start cycling again. This creates a mental and behavioural threshold that varies across individuals, making aggregate demand more sensitive to small changes in weather and therefore harder to model accurately. The relatively poor performance in March, April, and December is therefore likely to reflect both model limitations and data limitations: the model omits factors such as rainfall, wind, holidays, and special events, while the available predictors may not fully explain abrupt seasonal changes in cycling behavior.

5.2.3 Long-term trend and extrapolation

Table 7: Trend coefficients from models M1–M3.

Model	Daily.change..cyclists.day.	Annual.change..cyclists.year.
M1	-1.895	-692
M2	-1.872	-683
M3	-2.152	-786

Table 8: Statistical significance of the trend coefficient in models M1–M3

Model	Estimate	Std_Error	t_value	p_value
M1	-1.8945	0.1392	-13.61	0
M2	-1.8724	0.1390	-13.47	0
M3	-0.0002	0.0000	-13.92	0

Tables 7 and 8 show that all three models estimate a statistically significant negative trend. M1 implies 692 fewer cyclists per year, M2 683, and M3 786, corresponding to annual percentage changes of -5.66%, -5.48%, and -6.82% relative to the predicted count on 1 January 2020. Table 9 shows the trend is consistent across

Table 9: Annual growth rate expressed relative to the predicted count on 1 January 2020.

Model	Predicted_start_count	Daily_change	Annual_change	Growth_percent
M1	12222.3	-1.895	-692	-5.66
M2	12462.5	-1.872	-683	-5.48
M3	11512.3	-2.152	-786	-6.82

models, though the slightly more negative estimate in M3 suggests skewness and non-constant variance shift the implied rate somewhat.

Table 10: Comparison of M3 trend estimates with and without a COVID indicator.

Model	Daily_change	Annual_change
M3	-2.152	-786
M3 + COVID	-2.904	-1060

Table 10 shows that including a COVID indicator shifts the M3 trend from -2.152 to -2.904 cyclists/day (-786 to -1060 per year), so the trend should not be read as evidence of structural decline.

Figure 10: Extrapolation of Cycling Demand

Table 11: Earliest projected date at which predicted summer weekday demand exceeds 15,000 cyclists/day.

date	pred_count
2020-01-01	15578.52

The extrapolation based on M3 projects decline in Figure 10, rather than an increase, summer weekday cycling demand through to 2035. Using the fitted model we can see that the predicted demand is already above the 15,000 cyclists/day threshold at the start of the period, starting at an estimated value of 15,579 on 1 January 2020 as seen in Table 11. It then falls steadily, where in 15 years, the estimated value for cyclists/day is 5,300. This means that, at the current fitted rate, the model does not predict future growth toward the threshold; instead, it suggests that demand moves away from it over time.

This kind of long-run extrapolation should be treated with caution for at least two reasons. First, the

fitted linear trend is estimated over a short period, specifically the COVID-19 disruption, where many were forced to stay indoors, hence it may not represent the true long-term path of cycling demand. Secondly, the projection holds weather and seasonal conditions fixed and ignores other factors that could substantially alter future demand. Notably as infrastructure investment, policy changes, fuel prices, or changes in population and commuting patterns. For these reasons, the extrapolation is useful as a simple model-based scenario, but not as a reliable long-term forecast.

5.2.4 Identifying a poorly-fit period

This subsection examines the residuals of the final model over time in order to identify a specific period in which the model performs notably poorly. The aim is to determine whether the model systematically over- or under-predicts during that period, and to consider what that implies from both a statistical and transport-planning perspective.

Figure 11: Residuals over Time

Figure 11 identifies periods where the final model appears to fit particularly poorly. This can be caused either by residuals that are unusually large in magnitude or because they are persistently positive or negative over a sustained interval.

Table 8 shows the months in which the final model performs worst, ranked by period-specific RMSE. This table will therefore help indicate the exact month with worst performance.

From Table 12, we find that April 2022 stands out as the single poorest-fitted month. It has the largest month-specific RMSE in the table, equal to 11317.8, and a positive mean residual of 8934.4. This indicates that the model under-predicts cyclist demand consistently during this period of time rather than making a few isolated large errors.

This implies April 2022 was a period of unusually high cycling demand that is not fully explained by the variables included in the model. The residual plot shows a large grouping of positive residuals during spring

Table 12: Months with the largest RMSE under the final model.

year_month	mean_residual	RMSE
2022-04	8934.418	11317.815
2022-03	6851.281	10416.665
2024-12	6009.515	7866.465
2022-08	3602.210	7861.138
2022-05	4191.181	7662.392
2024-10	5446.711	5885.668
2025-01	4548.762	5858.492
2022-01	1747.584	5774.558
2024-11	4927.126	5598.794
2024-09	4922.280	5233.538

and summer 2022. This suggests that the model may be missing some factor that lifted counts above their usual seasonal level.

From a transport-planning perspective, this reflect changes in travel behavior, especially if cycling demand temporarily increased because of favorable or unfavorable conditions. There was potentially a post-pandemic behavioural shifts, where increased free movement was taken advantage. On the other hand, there may have been external factors such as fuel prices. The Ukraine-Russia war started in Feb.2022 and had resulted in significant increases in the prices of crude oil. Statistically, the poor fit also reflects model limitations: the final model includes temperature, seasonality, day of week, and trend, but omits potentially important short-term drivers such as rainfall, wind, holidays, oil prices and special events. April 2022 therefore appears to be a period where both the data limitations and the model specification contribute to poor predictive performance.

5.5 Original Diagnostic Plot

This subsection presents an original plot that is not a standard diagnostic, designed to reveal an interesting feature of the final model that is not visible from standard diagnostics plots. This plot tracks the monthly mean residual over time, showing whether the model systematically over- or under-predicts demand in different periods

Figure 12: Monthly Mean Prediction Bias

The plot in Figure 12 shows the monthly mean residual of the final model over time. Positive values indicate systematic under-prediction and negative values indicate systematic over-prediction. Multiple periods are

visibly out, particularly parts of 2022 and late 2024, where the model persistently under-predicts cycling demand, while much of 2025 shows negative mean residuals, indicating over-prediction. A transport planner should conclude that the model captures overall demand patterns reasonably well, but it struggles to track shifts in underlying behaviour across time. In particular, some periods appear to involve sustained changes in demand that are not fully explained by temperature, seasonality, day of week, and trend alone.

This plot is useful because it highlights regional bias rather than just overall error magnitude. Unlike RMSE or QQ plots, it shows when the model is persistently wrong in one direction, which is especially important for planning. A model that repeatedly under-predicts demand during certain periods may lead planners to underestimate pressure on cycling infrastructure, while persistent over-prediction could lead to over-allocation of resources.

6 Discussion and limitations

Of the four models fitted, M3 comes closest to satisfying the standard linear regression assumptions, though none fully does. M0 through M2 all show indications of heteroscedasticity and a heavy right tail in the QQ plot, which are unsurprising given that daily cyclist counts are non-negative and right-skewed by nature. The log transformation in M3 largely addresses both problems — residuals are much more evenly spread and the QQ plot follows the reference line well across most of its range — but some deviation remains at both tails, so the Gaussian assumption should still be interpreted with some caution even for M3.

The main limitation of the data is that it only includes temperature and calendar variables. Rainfall and wind in particular are likely to affect whether people choose to cycle on a given day, yet neither is available in the dataset. This probably explains why the model struggles most in March and April, and why it consistently under-predicted demand during spring and summer 2022 — periods where something beyond temperature and seasonality was clearly driving behaviour. A separate issue is that the response variable pools counts across all monitoring stations, so the model cannot distinguish between commuter routes and leisure routes, which likely behave quite differently.

The long-term trend is also harder to interpret than it first appears. Fitting a single linear trend across 2020–2025 forces the model to average over the COVID dip, the recovery period, and the later years all at once. As the COVID indicator comparison in Section 5.3 shows, this matters — the trend estimate shifts noticeably depending on how the pandemic period is treated, so the negative trend should not be read as straightforward evidence that cycling in Edinburgh is in structural decline.

The most practical improvements would be to add precipitation and wind speed as predictors, and to replace the linear trend with something more flexible such as a piecewise specification that separates the pandemic period from the rest. A Poisson or negative binomial model would also be a more natural fit for count data and would avoid the back-transformation issue that inflates the DS and IS scores for M3. Longer term, disaggregating to individual monitoring stations would allow more targeted conclusions about specific routes and corridors.

Finally, it is worth being cautious about how far these findings extend beyond Edinburgh. The temperature effects, commuter patterns, and trend estimate reflect a specific city during an unusual five-year period. A city with a warmer climate or a different cycling culture might show very different seasonal patterns and temperature sensitivity. Even for Edinburgh, the short observation window means the trend extrapolation to 2035 should be treated as an illustrative scenario rather than a forecast — particularly given how much the pandemic distorts the earlier part of the data.

7 Appendix: Code

All analysis code is in `code.R` and is reproduced below.
